We apply quantum control techniques to control a large spin chain by only acting on two qubits at one of its ends, thereby implementing universal quantum computation by a combination of quantum gates on the latter and swap operations across the chain. It is shown that the control sequences can be computed and implemented efficiently. We discuss the application of these ideas to physical systems such as superconducting qubits in which full control of long chains is challenging.

PACS numbers: 03.67.-a, 02.30.Yy

Controlling quantum systems at will has been an aspiration for physicists for a long time. Achieving quantum control not only clears the path towards a thorough understanding of quantum mechanics, but it also allows the exploration of novel devices whose functions are based on exotic quantum mechanical effects. Among others, the future success of quantum information processing depends largely on our ability to tame many-body quantum systems that are highly fragile. Although the progress of technology allows us to manipulate a small number of quanta quite well, controlling larger systems still represents a considerable challenge. Unless we overcome difficulties towards the control over large many-body systems, the benefits we can enjoy with the ‘quantumness’ will be severely limited.

One encouraging result is that almost any coupled quantum system is controllable in principle, even by steering a single particle only [1]. The question of controllability in this type of situation can be described by the theory of quantum control [2], which uses Lie algebraic arguments. This is interesting from the theoretical point of view; however, can it be practically useful from the quantum computing perspective? Problems we need to contemplate before attempting to build a large quantum computer using quantum control are as follows. First, the control criterion is generally not computable for large systems. Second, even if the question of controllability can be answered positively for specific systems [3], the precise sequence of actual controls (or ‘control pulses’) are generally not computable. And third, even if they can be computed, the theory of control tells us nothing about the overall *duration* of the control pulses to achieve a given task, and it might take far too long to be practically relevant.

The usual approach to circumvent these problems focuses on systems that are sufficiently small, so that we do not already require a quantum computer to check their controllability and to design control pulses. In such a case, the theory of time optimal control [4] can be used to achieve impressive improvements in terms of total time or type of pulses required in comparison with the standard gate model. More complicated desired operations on larger systems are then decomposed

Figure 1: (color online) Our approach for universal quantum computation works on a chain of N spins. By modulating the magnetic field $B_1(t)$ on qubit 1, we induce information transfer and swap gates on the chain (red and green lines). The states of the qubits from the uncontrolled register can be brought to the controlled part. There, the gates from a quantum algorithm are performed by local operations. Afterward, the (modified) states are swapped back into their original position.

(‘compiled’) into sequences of smaller ones. Yet, the feasibility of this approach is ultimately limited by the power of our classical computers, therefore constrained to low-dimensional many-body systems only.

The first step to achieve control over large-scale systems by controlling only a few particles was done in the context of quantum state transfer in spin chains. In these simple models, the issues mentioned above were avoided by restricting the analysis to the subspace with a single excitation. Most of the proposed schemes for quantum state transfer [5, 6] are not actually based on the framework of control theory, but on smart tricks from various fields of physics, often using classical intuition about the dynamics. Also, the theory of optimal control was recently applied to state transfer [7, 8].

A few of these proposals were then applied to more general tasks than state transfer; that is, how to use spin chains for entanglement purification [9], cloning transformations [10], or even for fully fledged quantum computation with little control [6]. Thus, such schemes are no longer restricted to a small subspace of the full Hilbert space. These schemes for quantum computation use clever methods to design the control pulses analytically, i.e., without relying on control theory,

but at the price of limitations on their applicability. In particular, they assume specific coupling parameters and design of the system. Nonetheless, such methods are intriguing from a theoretical perspective (e.g., in relation to complexity questions) and give hope for the feasibility of quantum control of larger systems.

The goal of this paper is to efficiently compute control pulses for a large system, using the full Hilbert space, and to show that the duration of the pulses scales efficiently (i.e., polynomially) with the system size. There are various trade-offs to consider. For instance, if we allow more means for external control and/or higher ability in designing the system Hamiltonian, the problem will become more tractable theoretically (on paper), but more demanding and less relevant from an experimental perspective.

Here, we present a solution to achieve feasible control both theoretically and experimentally. We will use a Hamiltonian that can be efficiently diagonalized for large systems through the Jordan-Wigner transformation. The control pulses are applied only to the *first two* spins of a chain (see Fig. 1). The control consists of two parts: one where we will use the Jordan-Wigner to efficiently compute and control the information transfer through the chain (thus using it as a quantum data bus), and a second one where we will use some local gates acting on the chain end to implement two-qubit operations. To be efficiently computable, these local gates need to be fast with respect to the natural dynamics of the chain. Combining the two actions allows us to implement any unitary operation described in the gate model. The interplay of the Jordan-Wigner picture for the information transfer and the gate model in the canonical basis will also require some tricks to avoid the accumulation of (uncomputable) phases.

System and information transfer problem.— We consider a chain of N spin-1/2 particles coupled by the Hamiltonian

$$H = \frac{1}{2} \sum_{n=1}^{N-1} c_n [(1+\gamma)XX + (1-\gamma)YY]_{n,n+1} + \sum_{n=1}^N B_n Z_n,$$

where X, Y, Z are the Pauli matrices, the c_n are generic coupling constants and B_n represent a magnetic field. Varying the parameter γ allows to encompass a wide range of experimentally relevant Hamiltonians [11, 12, 13], including the transverse Ising model ($\gamma = 1$; for this case we require the fields $B_n \neq 0$) and the XX model ($\gamma = 0$). We assume that the value of the first magnetic field, B_1 , can be controlled externally. This control will be used to induce information transfer on the chain and realize swap gates [22] between arbitrary spins and the two ‘control’ spins 1, 2 at one chain end. Hence such swap gates are steered *indirectly* by only acting on the first qubit. The tunable parameter will also be used for applying unitaries on the control spins.

In order to focus on the main idea we now present our method for $\gamma = 0$ and $B_n = 0$ for $n > 1$. The general case follows along the same lines, though being more technically involved. Our first task is to show that by only tuning $B_1(t)$, we can perform swap gates between arbitrary

pairs of qubits. First we rewrite the Hamiltonian, using the Jordan-Wigner transformation $a_n = \sigma_n^+ \prod_{m < n} Z_m$, into $H = \sum_{n=1}^{N-1} c_n \{a_n^\dagger a_{n+1} + a_{n+1}^\dagger a_n\}$. The operators a_n obey the canonical commutation relations $\{a_n, a_m^\dagger\} = \delta_{nm}$ and $\{a_n, a_m\} = 0$. The term we control by modulating $B_1(t)$ is $h_1 = Z_1 = 1 - 2a_1^\dagger a_1$. From the theory of quantum control [2] we know that the reachable set of unitary time-evolution operators on the chain can be obtained from computing the *dynamical Lie algebra* generated by ih_1 and iH . It contains all possible commutators of these operators, of any order, and their real linear combinations. For example, it contains the anti-Hermitian operators $ih_{12} \equiv [ih_1, [ih_1, iH]]/(4c_1) = i(a_1^\dagger a_2 + a_2^\dagger a_1)$, $ih_{13} \equiv [iH, ih_{12}]/c_2 = a_1^\dagger a_3 - a_3^\dagger a_1$ and $ih_{23} \equiv [ih_{12}, ih_{13}] = i(a_2^\dagger a_3 + a_3^\dagger a_2)$. We observe that taking the commutator with h_{12} exchanges the index 1 of h_{13} with 2. Taking the commutator with iH we find that $ih_{14} \equiv [ih_{13}, iH] + ic_1 h_{23} - ic_2 h_{12} = i(a_1^\dagger a_4 + a_4^\dagger a_1)$ and $ih_{24} \equiv a_2^\dagger a_4 - a_4^\dagger a_2$ are also elements of the dynamical Lie algebra. Hence the effect of taking the commutator with H is raising the index of the h_{kl} . Generalizing this, we find that the algebra contains the elements ih_{kl} , with $k < l$, $ih_{kl} \equiv a_k^\dagger a_l - a_l^\dagger a_k$ for $(k-l)$ even, $ih_{kl} \equiv i(a_k^\dagger a_l + a_l^\dagger a_k)$ for $(k-l)$ odd, and $h_k = Z_k = 1 - 2a_k^\dagger a_k$. From control theory [2] we thus know that the time evolution operators $\exp(-3\pi i h_{kl}/2)$ (which will turn out to be very similar to swap gates) can be achieved through tuning $B_1(t)$. The main point is that because both h_1 and H are free-Fermion Hamiltonians, the corresponding control functions can be computed *efficiently* in a $2N$ -dimensional space (we will do so explicitly later). Ultimately, we need to transform the operators back to the canonical spin representation. Using $a_k^\dagger a_l = -\sigma_k^- \sigma_l^+ \prod_{k < j < l} \sigma_j^z$, we find $\exp(-\pi i h_{kl}/2) = (|00\rangle_{kl}\langle 00| + |11\rangle_{kl}\langle 11|) \otimes \mathbb{1} + (|01\rangle_{kl}\langle 10| - |10\rangle_{kl}\langle 01|) \otimes L_{kl}$ for $(k-l)$ odd. The operator $L_{kl} = \prod_{k < j < l} \sigma_j^z$ arises from the non-local tail of the Jordan-Wigner transformation and act only on the state of the spins *between* k and l . They are *controlled* by the state of the qubits k, j being in the odd parity sector.

In order to use the chain as a quantum data bus, our goal is to implement *swap gates* $S_{kl} = |00\rangle_{kl}\langle 00| + |11\rangle_{kl}\langle 11| + |10\rangle_{kl}\langle 01| + |01\rangle_{kl}\langle 10|$, so the fact that we have achieved some modified operators with different phases on k, l instead, and also the controlled non-local phases L_{kl} , could potentially be worrisome. It is worth pointing out that the XX interaction is not capable of generating swap gates of the (physical) qubits. We will use a method suggested in [14] that allows us to tackle these complications. That is, rather than using the physical qubits, we encode in *logical* qubits, consisting of two neighbouring physical qubits each. They are encoded in the odd parity subspace $|01\rangle, |10\rangle$. Swapping a logical qubit n to the control end of the chain then consists of two physical swaps $\exp(-\pi i h_{1,2n-1}/2)$ and $\exp(-\pi i h_{2,2n}/2)$. Since both physical swaps give the same phases, the resulting operation is indeed a full logical swap. Any single-qubit operation on the logical qubits can be implemented by bringing the target qubit

to the control end, performing the gate there, and bringing it back again. If we modulate the magnetic field $B_1(t)$, we could equally decide to perform single logical qubit gates directly, without bringing them to the control end. This is possible because $\exp(-i\hbar_{2n-1}2nt)$ in the physical picture translates to $\exp(-iX_{L,n}t)$ in the logical picture, and because Z_{2n-1} is in the algebra generated by Z_1 , which allows us to perform the operation $\exp(-iZ_{2n-1}t) = \exp(-iZ_{L,n}t)$.

For quantum computation, we need to be able to perform at least one entangling two-qubit operation. We choose a controlled-Z operation, as this can be performed by operating only on half of two logical qubits. That is, to perform a controlled-Z between logical qubit n and m , we bring the physical qubits $2n-1$ and $2m-1$ to the control end, perform a controlled-Z between them, and bring them back. It is easy to check that again all unwanted phases cancel out. The controlled-Z could not be efficiently computed in the interplay with the many-body Hamiltonian H , because it cannot be generated by a quadratic Hamiltonian in the Jordan-Wigner picture. Therefore, this gate has to be implemented on a time-scale t_g much faster than the natural evolution of the chain, i.e., $t_g \ll \min_j \{1/c_j\}$. We can soften this requirement by using control theory to generate $\exp(-iZ_1X_2t)$ by modulating $\beta_1(t)Y_1$ (this is a linear term in the Jordan-Wigner picture), and then using a fast Hadamard gate on the second site to obtain $\exp(-iZ_1Z_2t)$, which, together with $\exp(-iZ_1t)$ and $\exp(-iZ_2t)$, gives the controlled-Z gate. This gives us quite a remarkable conclusion: except for a fast Hadamard on a single qubit, all other controls required for quantum computation can be computed efficiently in the Jordan-Wigner picture.

Efficiency.— The crucial question left open in the above is: how long does it actually take to implement the gates? Unfortunately, the theory of quantum control does not provide a general answer, though some interesting progress was recently reported [19]. In order to evaluate the efficiency, we have numerically simulated a range of chain lengths and studied the scaling of the logical swap operation time T with the (physical) chain length N . For the control, we choose the local magnetic field $B_1(t)$ at the first site. We set the coupling strength constant, namely $c_n = J \forall n$. To provide evidence of a polynomial scaling, we set the simulation time $T_N = (N-1)^2$, (all times are given in units of $1/J$ and $\hbar = 1$) and verify for each N that we can find a specific $B_1^*(t)$ that performs the logical swap [23]. We quantify our success by calculating the error of the operation $\varepsilon = 1 - F$, where $F = (|\text{tr} U^\dagger U_g|/N)^2$ is the fidelity between the time evolution U and the goal unitary U_g . We find the function $B_1(t)$ using techniques from optimal control theory [2, 4, 15]. Briefly, the procedure is as follows: (1) an initial guess is made for the function $B_1(t)$; (2) we run the optimal control algorithm to generate a new $B_1(t)$ which decreases the error of our operation; (3) steps 1 and 2 are iterated until the final error reaches a defined threshold ε . In practice, it suffices to choose a threshold which is of the same order of magnitude as the error introduced by the Hadamard gate.

If the algorithm converges for each N and the correspond-

Figure 2: (color online) The optimized function $B_1^*(t)$ that produces the physical swap between $n=1$ and $n=29$ for the chain $N=30$ in a time T_{30} (in units of $1/J$). The inset shows a zoom to confirm that the time-scale of the oscillations of $B_1^*(t)$ are slower than the dynamics of the chain.

ing T_N , giving the optimal pulse sequence $B_1^*(t)$, then we can assert that the scaling of the operation time is at least as good as $T_N = (N-1)^2$, up to a given precision. We initialize the algorithm with a guess for the function $B_1(t)$, e.g., $B_1(t) = 1$. This is, of course, a rather poor choice for performing the swap gate. However, the optimization algorithm exponentially improves the choice of $B_1(t)$ reaching, after several thousand iterations, the desired precision. A typical optimized function $B_1^*(t)$ is given in Figure 2. It is worth pointing out that although the pulse *looks* like it is oscillating very rapidly, its oscillations are slower than the natural dynamics of the chain, thus the control function does not need to be fast. Indeed, a Fourier analysis confirmed that only frequencies of up to $\sim 0.02J$ are required. Furthermore, such pulses are robust against small fluctuations [4]. The results of the optimizations for different chain lengths are shown in Figure 3: the desired quadratic scaling has been clearly achieved. We stress here that the chosen scaling law T_N may not necessarily describe the shortest time on which the physical swap gate can be performed. However, the dynamical Lie algebra of quasi-free fermions has a dimension of the order N^2 , indicating that such scaling might be optimal. Note that even though here we focused on swapping between the chain ends, which one expects to take the longest time, we checked that general swaps between any pair of logical qubits can be achieved in (at least) the same time-scale (data not shown).

A final remark on the robustness against imperfections of the results presented is needed, as perfect homogeneity or even fine tuning of individual couplings might be very hard to achieve in most systems and might prevent information transfer schemes to work [16]. In the previous analysis, for simplicity, we considered a chain with uniform couplings $c_n = J$ for $n > 1$, but the results for arbitrary couplings are similar as long as localization effects can be neglected. We assume that the disordered Hamiltonian parameters are known, because they can be estimated efficiently by controlling only the chain end [17, 18]. We checked that the optimization with off-site disorder of 10%, uniformly distributed, leads to the same

Figure 3: (color online) The swap operation time T_N versus the chain length N : the red continuous line is $(N - 1)^2$ while the black dots are the lengths for which we numerically verified this scaling with an error $\varepsilon < 10^{-4}$.

results, for most realizations, until at least $N = 40$.

Conclusion.— We have shown how to *efficiently* compute control pulses for large spin chains described by a vast class of Hamiltonians. The pulses are computed for an $2N$ -dimensional system but can be applied to the full 2^N -dimensional system. Full quantum computation is possible by only controlling *two* spins at one end of the chain. The only price for this indirect control is that the quantum computation takes quadratically longer than for direct control. Given the large benefit of requiring so little control for a quantum computer, we believe that this scheme would be very useful for future implementations. As a further application, we remark that our proposal can also be applied to use the spin chain as a quantum memory, storing qubits by moving states from the controlled part to the rest of the chain and by applying control pulses on qubits 1, 2 to achieve the identity on the register (effectively switching off the chain Hamiltonian). For future studies, we would additionally like to probe the ultimate limit at which one may perform swaps using optimal control [2, 4, 8, 15], and try to obtain simple (possibly analytic [19]) pulses.

As a possible application of our proposal, we note that in Josephson qubit implementations, much progress has been reported on the control of two-qubit gates [11], but that controlling and reading out many qubits is very hard. In fact, it is expected to be difficult to construct fully addressable long arrays of Josephson junctions while it is conceivable to produce long chains of qubits with always-on interaction where only one or two qubits are fully controllable and readable [24]. In those systems the decoherence time is (optimistically) ~ 1000 times larger than the time-scale of the inter-qubit coupling [20, 21], which would make our scheme applicable for up to ~ 30 qubits to achieve a single swap gate (though, of course, much less to achieve full computation). Hence, the optimal control ideas presented here have the potential to address a serious limitation in such implementations and thus open a novel avenue towards quantum information processing in solid state devices.
